## **Abstract**

The spatial distribution of droplets in a spray cloud created by wave-impact sea spray and the distribution of their sizes and velocities over a vessel deck is investigated. Wave-impact sea spray, which occurs due to striking high energy sea waves on a vessel's bow, creates numerous droplets in front of a vessel. Droplets are frequently the result of sheet and droplet breakup of sea water. The velocity-size dependence of the resultant droplets is important in the modelling of marine icing phenomena. A droplet trajectory method employs the velocity-size dependence of the droplets to find their spatial distributions in the cloud of spray over the vessel deck. Drag body forces overcome the initial velocities of the droplets so they follow the wind direction and gravitational direction. The motion of the droplets affects the shape and extent of the spray cloud in front of the vessel and over the deck. In this paper, numerical methods are developed to find the distribution of sizes and velocities of the droplets over a vessel. Results show that neither the smallest nor the largest droplets reach the maximum height. The medium-size droplets can reach the maximum height of the spray cloud. As the spray cloud travels over the deck, the droplet velocities become almost the same. Comparing the numerical results with field observations shows

28

## 29 **1. Introduction**

30 Wave-impact sea spray, which results from high energy sea waves striking a vessel bow or hull,  
31 is the main reason for marine icing in cold regions (Zakrzewski, 1987; Lozowski et al., 2000;  
32 Panov, 1978). Every spray cloud carries numerous droplets towards the vessel platform  
33 (Zakrzewski, 1986; Zakrzewski and Lozowski, 1988). The nature of the spray cloud and droplets  
34 affects the progress of ice accretion on a marine vessel (Ryerson, 1995; Borisenkov et al., 1975).  
35 A spray cloud can be defined based on time dependent spatial distributions of sizes and velocities  
36 of the droplets. The spatial distributions, including the velocity and size of the droplets, determine  
37 the spray cloud (Zakrzewski and Lozowski, 1988; Dehghani et al., 2016a).

38         Apart from the ambient temperature, relative humidity and wind velocity, the incoming  
39 water flux to a vessel deck is important for calculating the amount of accumulated ice on the vessel  
40 (Kulyakhtin and Tsarau, 2014; Horjen, 2013). The accumulated ice is brine-spongy ice (Dehghani  
41 et al., 2016b). The water flux varies with position and time. Size and velocity distributions of the  
42 droplets in a spray cloud determine the local spray flux at every point of a vessel. Distributions of  
43 size and velocity will yield the water flux, which will also be a function of time and space  
44 (Dehghani et al., 2016a).

45         Past studies reported mono-size models where there is no distribution of size and velocity  
46 for a cloud of spray (Kulyakhtin and Tsarau, 2014). Horjen (2013) used a size of 1.8 mm for the

47 droplets. Shipilova et al. (2012) assumed 0.25 mm and 2 mm as the droplet sizes. Horjen (2015)  
48 considered the size of the droplets as 3.8 mm. Chung and Lozowski (1998) assumed the same size  
49 of droplets as Zakrzewski (1986), 1.75 mm. Kulyakhtin and Tsarau (2014) mentioned that droplet  
50 sizes are between 1 and 2 mm. These past studies assumed the initial velocity of the droplets as  
51 equal to the wind velocity. A lack of distribution of size and velocity in a spray cloud led the  
52 researchers to use mono-size and mono-velocity models.

53 Droplet trajectory models can predict the droplet paths and consequently their positions.  
54 When a spray cloud moves, droplets start their movements at their initial positions and finish by  
55 impinging on vessel surfaces (Dehghani et al., 2009; Zakrzewski and Lozowski, 1988). The droplet  
56 trajectory method, which needs the initial size and velocity distributions, will determine the  
57 distribution of the size and velocity of the droplets at every section of the spray cloud, and  
58 consequently, the final distribution of the spray flux over the vessel surfaces (Dehghani et al.,  
59 2013; Dehghani et al., 2016a).

60 The liquid water content (LWC) of a spray cloud over a vessel deck is affected by the  
61 distributions of size and velocity of droplets over a vessel platform (Ryerson, 1995; Dehghani et  
62 al., 2016a). The collision efficiency, which is a key parameter in calculating the fraction of  
63 impingement of the droplets on a specific surface, is also a function of the size and velocity of the  
64 droplets close to the surface (Zakrzewski, 1986). The freezing rate can be affected by the incoming  
65 flux of water and the collision efficiency. Both are also dependent on the distribution of size and  
66 velocity of droplets (Chung et al., 1998a; Chung et al., 1998b; Sharpov, 1971; Shipilova, et al.  
67 2012).

68 Therefore, determination of the distributions of size and velocity of the droplets and their  
69 variations over marine vessels during the motion of a spray cloud are essential for accurate

70 modelling of marine icing phenomena (Zakrzewski and Lozowski, 1988). The assumptions of  
71 constant droplet sizes and velocities used in previous models of marine icing are not satisfactory.  
72 This assumption does not yield a sufficiently accurate estimation of ice accretion over a marine  
73 vessel. A vertically uniform size and velocity are the most common assumption in past studies  
74 (Horjen, 2013; Horjen, 2015; Kulyakhtin and Tsarau, 2014; Lozowski et al., 2000; Shipilova, et  
75 al., 2012).

76 This paper focuses on new models for the distributions of size and velocity of droplets in  
77 a spray cloud over a marine vessel, using a droplet trajectory method and droplet-size-dependent  
78 characteristics after water breakup in front of a vessel. A new distribution of size and velocity is  
79 presented. The distribution of size and velocity can determine the extent of the spray cloud over a  
80 vessel. The model will be examined and compared against data from field observations.

81

## 82 **2. Spray Cloud Processes**

83 Wave-impact sea spray is created by high energy sea waves striking a vessel bow or hull (Dehghani  
84 et al., 2016a; Zakrzewski, 1986). The process of creating a spray cloud and its development and  
85 motion can be divided into several stages: wave impact, sheet breakup, droplet breakup, spray  
86 cloud formation, spray cloud acceleration and deceleration, and spray cloud fall and impingement.  
87 These stages have not been well understood (Dehghani et al., 2016a; Ryerson 1995). The  
88 mechanism of sheet creation, sheet breakup and droplet breakup have been examined in a few past  
89 studies but need more investigation (Bullock et al., 2007; Galiev and Flay, 2014; Greco et al.,  
90 2013; Gu et al., 2014; Ren and Marshall, 2014; Dehghani et al., 2016a).

91 After the stage of droplet breakup, there are numerous droplets with various sizes and  
92 velocities in the spray cloud. At the front edge of the vessel, the droplets are moving upward and

93 in the same direction as the vessel. The stage of spray cloud formation begins with decelerating  
94 and accelerating droplets. Upward movement of the droplets is decelerated by drag forces and  
95 body forces. Drag forces are created as a result of the relative velocity of the droplets and wind.  
96 Body forces occur with the gravity force exerted on the droplets. Due to the drag force and body  
97 force, the vertical component of droplet velocities decreases to reach zero. At this point, droplets  
98 reach their maximum height. The horizontal components of the droplet velocities experience the  
99 same trend. The start of the horizontal movement of the droplets is usually in the opposite direction  
100 of the wind velocity. The wind slows down the droplets. After a short period, in the decelerating  
101 period, the horizontal velocities of the droplets become zero. This point is the maximum horizontal  
102 development of a spray cloud in the opposite direction of the wind.

103 Droplets with a vertical velocity of zero, which are at their maximum heights, start  
104 downward movement because of gravity. This accelerates the droplets to reach their terminal  
105 velocities. The droplets with zero horizontal velocities are affected by the wind velocity and  
106 increase their velocities. The wind accelerates these droplets and increases their velocities to the  
107 wind velocity. Accelerating the droplets is continued until the droplets impinge on the vessel  
108 surfaces.

109 The spray cloud fall and droplet impingement are the last stages of motion of a spray cloud  
110 over a marine vessel. The various droplets with various sizes and velocities take different paths  
111 and reach different positions. The drag force, wind velocity, droplet size, and initial velocity of  
112 droplets determine the trajectory of the droplets. Figure 1 illustrates these stages of a spray cloud  
113 development related to wave-impact sea spray over a marine vessel. The vessel chosen is the same  
114 as a Medium-size Fishing Vessel (MFV) (Borizenkov et al., 1975; Zakrzewski, 1986; Sharpov,  
115 1971). The important components of the MFV are illustrated in the figure. The overall length of

116 the vessel is about 39.5 m. The foremast is located at 11.0 m from the ship bow. The front side of  
 117 the structure is located at a distance of 19.2 from the ship bow. The height of the structure above  
 118 the deck is 4.5 m. The life boat is located 29.0 to 34.1 m from the ship bow (Zakrzewski and  
 119 Lozowski, 1988).

120 The initial velocities and sizes of droplets at the front edge of a marine vessel are among  
 121 the most essential elements for predicting the droplet trajectories. A velocity-size dependence  
 122 suggests that after the droplet breakup stage, the larger droplets have lower velocities and the  
 123 smaller droplets have higher velocities. This means at the front edge of the vessel, there is a  
 124 velocity-size dependence for the droplets that can be used for the initial conditions. Dehghani et  
 125 al. (2016a) reported this velocity-size dependence.

126

### 127 **3. Formulation of Spray Cloud Motion**

128 Spherical droplets, having a density of  $\rho_d$  and a diameter of  $D_d$ , are small compared to the  
 129 flow length scale (the bow dimension). Applying Newton's Second Law for the droplet motion  
 130 and substituting the body force and drag force will result in the following equation of the droplet  
 131 trajectory. The equation describing to droplet movement and the forces acting on them can be  
 132 expressed as:

$$133 \quad m_d \frac{d\mathbf{V}_d}{dt} = \rho_d \mathcal{V}_d \mathbf{g} - C_{dr} \frac{\pi D_d^2}{8} \rho_a |\mathbf{V}_d - \mathbf{V}_a| (\mathbf{V}_d - \mathbf{V}_a) + \rho_a \mathcal{V}_d C_{ad} \frac{D(\mathbf{V}_a - \mathbf{V}_d)}{Dt} + \rho_a \mathcal{V}_d \left( \frac{D\mathbf{V}_a}{Dt} - \right. \\
 134 \quad \left. \mathbf{g} \right) \quad (1)$$

135 where  $m_d$  is mass of the droplet,  $t$  is time,  $\mathbf{V}_d$  is droplet velocity,  $\mathbf{V}_a$  is air velocity,  $\rho_d$  is water  
 136 density,  $\mathcal{V}_d$  is droplet volume,  $\mathbf{g}$  is gravity,  $C_{dr}$  is drag coefficient,  $D_d$  is droplet diameter,  $\rho_a$  is air  
 137 density, and  $C_{ad}$  is added mass force coefficient. The coefficient  $C_{ad}$  is assumed to be 0.5 and  
 138  $C_{dr}$  can be calculated as follows (Dehghani et al. 2009):

$$C_{dr} = \begin{cases} \frac{24}{Re} & Re < 1 \\ \frac{24}{Re} (1 + 0.15Re^{0.687}) & 1 < Re < 1000 \\ 0.44 & Re > 1000 \end{cases} \quad (2)$$

In order to solve this equation, its unknowns are calculated separately. Substituting the unknowns leads to a set of ordinary differential equations as follows.

$$\dot{x} = \frac{dx}{dt}, \quad \ddot{x} = \frac{d^2x}{dt^2}, \quad \ddot{x} = -\frac{3C_{dr}}{4D(\gamma+C_{ad})}(\dot{x} - U)\sqrt{(\dot{x} - U)^2 + \dot{z}^2} \quad (3)$$

$$\dot{z} = \frac{dz}{dt}, \quad \ddot{z} = \frac{d^2z}{dt^2}, \quad \ddot{z} = \left(\frac{1-\gamma}{\gamma+C_{ad}}\right)g - \frac{3C_{dr}}{4D(\gamma+C_{ad})}(\dot{z})\sqrt{(\dot{x} - U)^2 + \dot{z}^2} \quad (4)$$

where  $x, \dot{x}, \ddot{x}, z, \dot{z},$  and  $\ddot{z}$ , are position, velocity, and acceleration of the droplets,  $\gamma$  is the liquid density to air density ratio, and  $U$  is the relative velocity of wind to the vessel. The initial conditions are droplet sizes and velocities. This set of six equations and six unknowns is solved with a standard numerical solver.

There are various suggested formulae for LWC due to wave-impact sea spray, but many are intended for offshore structures (Forest et al., 2005). The field observations of Borisenkov et al. (1975) are the most relevant data that can be used in this instance. These data related to the MFV which are suitable for our model and can be used to examine the droplet trajectory results. The proposed relation that represents the liquid water content is given by:

$$w = 24.2 \times \exp(-0.55z) \quad gr_{water}/m^3_{air} \quad (5)$$

where  $z$  is the elevation above the deck of the MFV (Zakrzewski, 1987) and  $w$  is the LWC.

#### 4. Numerical Results

The spray cloud motion can be quantified using the previous droplet trajectory model. Initial sizes of the droplets are chosen based on past work by Ryerson (1995), who reported the droplet sizes in a range from close to zero to 7.7 mm. Therefore, the initial distribution of sizes contains droplet

160 diameters from zero to 7 mm. The initial velocity distribution is chosen by considering the  
161 velocity-size dependence of the droplets at the end of water breakup. In this case, the maximum  
162 initial velocity is considered as 60 m/s. Therefore, there is a distribution of size and velocity that  
163 can be used as the initial condition at the front edge of the vessel. The model assumes that the wind  
164 velocity is uniform, horizontal and equal to 11 m/s, which is equal to the wind velocity of the MFV  
165 on the Sea of Japan as reported by Borisenkov et al. (1975). The heading angle is considered as  
166 180°. The ship velocity is assumed to be 2.83 m/s, which is equal to the MFV velocity on the Sea  
167 of Japan as reported by Borisenkov et al. (1975). The mass fraction of evaporation is assumed  
168 negligible. The spray is assumed dilute; therefore, the droplets will not affect each other and the  
169 droplet trajectory can be used for every droplet individually. The breakup is assumed to be finished  
170 at the vessel edge in front of the vessel.

171         The extent of the spray cloud is the first important parameter in the marine icing analysis.  
172 A high spray cloud can cause the creation of ice on the high elevations of the vessel. The  
173 accumulated ice on the high elevations changes the center of mass of the vessel to a higher level.  
174 This phenomenon causes an instability of the vessel that increases the risk of capsizing. Therefore,  
175 the height of spray is an important factor in the modelling of marine icing phenomena. Figure 2  
176 shows the results of the numerical solution, which are attached to the vessel sketch. The droplet  
177 trajectory method results in the creation of droplet paths over the deck. The dashed lines represent  
178 droplet paths over the vessel deck. The model calculates a full distribution of sizes and velocities  
179 as mentioned before. Figure 2 shows the trajectories of some droplets to represent the spray cloud.  
180 The spray cloud impinges on the foremast and the front side of the structure. Therefore ice  
181 accretion on these surfaces is expected. The spray cloud cannot reach the roof of the structure and  
182 the other areas that are far from the front of the vessel.

183           The largest and smallest droplets cannot reach the highest positions. Figure 2 shows that  
184 6.6 mm droplets fall to the deck very quickly. Their maximum heights are less than 0.2 m and their  
185 maximum ranges are less than 0.6 m. The maximum height for the droplets with a 0.3 mm diameter  
186 is about 1.5 m. The maximum height occurs for the medium-sized droplets. The droplets with 2.4  
187 to 3.8 mm diameter can reach the maximum height which is about 8 m and is located between the  
188 front edge of the vessel and the foremast.

189           The smaller droplets are rapidly affected by the wind. They are light and the wind can carry  
190 them more easily than heavy droplets. A competition between drag forces and the body forces  
191 determines the paths of the droplets. Larger droplets are heavy and lower velocity, while smaller  
192 droplets are light and higher velocity. Higher velocity droplets imply higher drag forces. Therefore,  
193 medium-size droplets are faced with values of body and drag forces that let them travel to the  
194 maximum height. The small and large droplets cannot reach the highest height because of their  
195 drag forces and body forces respectively.

196           Analyzing the vertical distribution of droplet sizes can clarify the extent of motion of the  
197 spray cloud. Figure 3 shows the size distribution of the droplets in the spray cloud in five cross  
198 sections. At  $x = 0$ , which occurs at the front edge of the vessel, the droplet size distribution  
199 includes droplets with sizes from 7 mm to very small droplets. The maximum height in this section  
200 is about 6 m. The larger and smaller droplets are at lower heights. The medium-size droplets can  
201 reach the high heights. At  $x = 5$  m, the maximum height of the spray cloud occurs. The maximum  
202 height is about 8 m. There are no droplets larger than 6 mm in this section. This means that 6 to 7  
203 mm droplets fall to the deck between  $x = 0$  and  $x = 5$  m. The next section,  $x = 10$  m, includes  
204 the droplet sizes smaller than 5.3 mm. The maximum height is less than 7 m. For the last section,  
205 the droplet sizes are limited to less than 4.6 mm. This means the larger droplets, which are heavier,

206 fall to the deck before reaching this section. As with the other sections, the larger and smaller  
207 droplets are at lower heights and the medium-size droplets can reach higher heights.

208 Vertical distributions of the droplet velocities are further important factors. Figure 4 shows  
209 the vertical distribution of the horizontal component of the velocity of the droplets in the five  
210 sections. In the first section, at  $x = 0$ , the distribution is completely different than the other  
211 sections. This section is located at the acceleration stage and the droplets are accelerated by the  
212 wind. The droplets are at the minimum horizontal velocities. The wind velocity will affect the  
213 droplets and carry them. The horizontal velocity of the droplets is expected to increase. In the next  
214 sections, the horizontal velocity increases. Figure 4 shows that the maximum velocity will be less  
215 than 14 m/s, which is very close to the relative velocity of the vessel and wind. The small droplets  
216 will have the same velocity as the wind after the second section. The difference between the  
217 horizontal velocities in each section decreases as  $x$  increases. This means the droplets tend to reach  
218 a uniform horizontal velocity as they travel over the deck.

219 The vertical distributions of the vertical components of the velocities of the droplets vary  
220 as the spray cloud travels. As with the horizontal velocity, the distribution of the vertical velocities  
221 in the section of  $x = 0$  is different. Droplets are decelerated to a zero velocity. In this section, the  
222 droplets move upward and the vertical velocity is positive. The maximum vertical velocity is less  
223 than 11 m/s. In the other sections, the droplets are falling. The minimum velocity is about 8.2 m/s.  
224 The differences between the vertical velocities of the droplets increase as they travel over the deck.  
225 They are affected by the forces, drag force and body force, in different ways.

226 The distributions of the total velocity of the droplets are shown in Figure 6. The total  
227 velocities vary between 0.4 and 14 m/s. For  $x = 0$ , the droplet velocities vary between 0.4 and  
228 12.4 m/s. This is the widest range of the velocities. Some droplets, the largest, have the lowest

229 velocity and some droplets, the smallest, have the highest velocity. The tightest range occurs for  
230  $x = 15 \text{ m}$ . In this section, the velocities of the droplets are about 14 m/s. As the spray cloud travels  
231 over the deck, the differences between the velocities decreases. The droplets correct their velocities  
232 and reach almost the same velocities after a short time.

233         As the spray cloud travels over the deck, large and low velocity droplets fall to the deck.  
234 Therefore, the LWC is expected to decrease. Figure 7 shows the variation of the LWC over the  
235 MFV at various  $x$  distances to the front edge of the vessel. The maximum amount of LWC occurs  
236 at  $x = 0$ , which is at the front of the vessel. At this point the variation of the LWC vs. height is  
237 approximately exponential. At  $x = 5 \text{ m}$ , the height of the spray increases but LWC decreases and  
238 the curve fluctuates between 3 and 4  $\text{gr}/\text{m}^3$ . At  $x = 10 \text{ m}$ , the height of the spray decreases and  
239 the LWC decreases as well. The LWC is about 1  $\text{gr}/\text{m}^3$  at  $x = 20 \text{ m}$ . This position is close to the  
240 front side of the structure of the vessel.

241         Droplet movements can be forward, which means co-flowing with the wind velocity,  
242 backward, which is a counter-direction with the wind velocity, upward, which is against gravity,  
243 and downward. The travel angle can define the type of movement. The angles between zero and  
244  $90^\circ$  mean forward-upward directions and the angles between zero and  $-90^\circ$  mean forward-  
245 downward directions. Figure 1 illustrates the definition of the travelling angle,  $\theta$ . Figure 8 shows  
246 the distributions of the traveling angles at various sections. At  $x = 0$ , the droplets are moving in  
247 forward-upward directions. This means the droplets are travelling towards the vessel and also  
248 towards the higher heights. All the droplets at  $x = 5 \text{ m}$  are travelling downward. This means they  
249 are in the stage of descent. As the spray cloud travels over the deck, the medium-size droplets  
250 move increasingly downward. This means the medium-size droplets are the last droplets that are  
251 affected by gravity.

252 Analyzing the distribution of size and velocity of the droplets can show that at the  
253 acceleration and deceleration stages, the droplets are expanding the spray cloud. After a full  
254 expansion, they start falling. The wind velocity affects the droplets in different ways. The smaller  
255 droplets are carried by wind and the larger droplets impinge on the deck rapidly.

256 The drag force is a key factor in analyzing the spray cloud movement. The drag force resists  
257 movement of the droplets in the air stream. The horizontal component of the drag force is a  
258 resistance force in the direction of the wind velocity. The maximum resistance occurs at the start  
259 of the development of the spray cloud when droplets are injected into the wind stream in the  
260 opposite direction. The drag force reduces the droplet velocities and decelerates them. The  
261 acceleration stage is started when droplets reach their minimum velocities. The droplets are  
262 accelerated and their velocities are increased over the deck. Figure 9 shows the distributions of the  
263 horizontal components of the drag forces of the droplets over the MFV. As the figure shows, the  
264 resistance force is higher at  $x = 0$ , especially for the small and high velocity droplets. This causes  
265 the droplets to reduce their velocities. At  $x = 5\text{ m}$ , the drag force decreases, the droplets are  
266 accelerated, and their velocities become close to the wind velocity. At  $x = 10, 15,$  and  $20\text{ m}$ , the  
267 situations are the same. The droplet velocities are closer to the wind velocity and the drag forces  
268 decrease. Figure 9 shows that the horizontal drag forces occur in the same direction as the wind  
269 velocity. This means the drag force helps droplets to be aligned with the wind throughout the  
270 process of the spray cloud development.

271 The vertical components of the drag forces affect the vertical movements of the droplets.  
272 At the start of the spray cloud formation, the vertical drag force is downward. This reduces the  
273 droplet velocities and prevents their further upward movement. The droplet velocities reach zero  
274 and then start falling down. At  $x = 0$ , the drag forces are negative and in the other sections the

275 drag forces are positive. At the start of the formation of the spray cloud, the vertical components  
276 of drag forces tend to reduce the upward velocities of the droplets. In the other sections, the  
277 droplets are falling down and the drag forces tend to resist their fall.

278 Figure 11 shows the distributions of the body forces in five sections over the deck of the  
279 MFV. The larger droplets have the higher body forces. The balance of the body force and the  
280 vertical component of the drag force determine the vertical movement of the droplets in the cloud  
281 of spray. The maximum body force occurs for the largest droplets, which are located at  $x = 0$ . As  
282 the spray cloud moves ahead, the large droplets fall down and the maximum value of the body  
283 forces reduces. Comparing Figs. 10 and 11 shows that as the spray cloud moves over the deck, the  
284 differences between the drag forces and body forces decrease. This shows that the droplets reach  
285 their terminal velocities in the last sections.

286 Figure 12 shows the distributions of the total drag forces in various cross-sections over the  
287 MFV. The maximum drag force occurs for the high velocity droplets at  $x = 0$ . These droplets that  
288 are the smallest sizes reduce their velocities in a short period. The drag force for the largest droplets  
289 is not the minimum drag in this section. The largest droplets have the smallest velocities and drag  
290 forces. The medium-size droplets that have a medium velocity and size have a moderate drag force.  
291 They are not heavy enough to be affected by gravity and they are not fast enough to be stopped by  
292 the drag force. This explains why they can reach the maximum height in the spray cloud. For the  
293 other sections, the drag forces decrease because of the lower relative velocities. The small droplets  
294 that have the same velocity as the wind have small drag forces.

295 The effect of the spray cloud on some parts of the MFV has been reported by Sharpov  
296 (1971). Table 1 shows a comparison between the results of the present model, observations of  
297 Sharpov (1971), and the results of Zakrazowski and Lozowski (1988). As shown in the table, the

298 wet height of the foremast, which is the minimum height of the foremast hit by the spray cloud, is  
299 predicted as about 6.28 m. In this situation, the prediction of Zakrazowski and Lozowski (1988) is  
300 about 5.85 m and the observation of Sharpov (1971) is between 5.9 and 7.9 m. The model predicts  
301 that the front side of the structure becomes wet. The wet height is about 2.33 m. The result of  
302 Zakrazowski and Lozowski (1988) is 2.07 m and Sharpov (1971) does not mention the wet height,  
303 but mentions that the spray hits the front side of the superstructure. The spray cloud cannot wet  
304 the other parts such as the roof of the structure, the boat deck, and the safety boat. The model,  
305 predictions and the observations are in a reasonable agreement.

306 Figure 13 shows a comparison between the LWC measured by Borisenkov et al. (1975)  
307 and the LWC obtained by the numerical model. The numerical results are well aligned with the  
308 measured results. The exponential form of the fitted curve of the observations is in useful  
309 agreement with the numerical results. The LWC corresponds to the section of  $x = 0$ , which is the  
310 front edge of the vessel. The maximum height of the spray at  $x = 0$  is about 6 m. Therefore the  
311 LWC varies at this height.

312 The model can be used to find the distribution of sizes and velocities in a cloud of wave-  
313 impact sea spray. The droplet trajectories of the droplets, by considering the drag and body forces,  
314 establish the paths and velocities of numerous droplets in the cloud of spray. The initial sizes are  
315 based on the velocity-size dependence of the droplets, which was reported by Dehghani et al.  
316 (2016a). The results of the numerical model will provide the dispersion of the droplets in front of  
317 the vessel and the way the spray cloud travels over the deck. The model can be used to determine  
318 the distributions of the sizes and velocities of the droplets in a cloud of spray. Using this model  
319 can help marine icing researchers to gain a better understanding of the incoming water flux at  
320 every point of a vessel.

321

## 322 **5. Conclusions**

323 Distributions of the droplet sizes and velocities were obtained by using velocity-size dependence  
324 of the droplets at the end of the breakup process and a droplet trajectory method. A vertical  
325 distribution of sizes shows that the assumption of uniform sizes for the droplets would not be  
326 accurate. The numerical results show that the smallest droplets, which are the high velocity  
327 droplets, are slowed down by drag forces rapidly. The largest droplets, which are the low velocity  
328 droplets, fall soon because of gravity. Therefore, medium-size droplets reach the highest  
329 elevations. The distribution of the vertical velocities of the droplets shows that the upward droplets  
330 change their movement to the downward direction after about 5 m traveling over the deck. The  
331 maximum velocity increases as the spray cloud moves on the vessel. The horizontal drag force is  
332 maximum at the stage of formation of the spray cloud. Drag forces change the droplet movement  
333 directions. Body forces are dominant forces in the vertical direction. The droplets are affected by  
334 the body forces and fall soon. Numerical results show that the maximum impingement height,  
335 predicted by the model, is aligned with the field observations reported by Sharpov (1971). The  
336 LWCs obtained by the numerical solutions are well aligned with the field observations reported  
337 by Borisenkov et al. (1975). The new model provides a useful method for estimating the size and  
338 velocity distribution in a cloud of spray.
