### ACKNOWLEDGERENTS

I wish to express my deep sense of gratitude to my supervisor, Professor P.D.P. Smith for his guidance and help during the course of

I am indebted to Dr. R. Tipping for suggesting the idea of shifting the reflection resonances within the quide.

I acknowledge the use of the computational work done by Dr. 6. Pedersen and Mr. Paul Gillard of MUN to predict the <sup>14</sup>NH, spectrum.

The financial support in the forms of the Memorial University of Newfoundland Graduate Fellowship and teaching assistantship is gratefully acknowledged.

#### ABSTRACT

Fifteen new ground state inversion lines of \$^{10}Mig\_were observed at 80° to 90°C, accurately measured and assigned. The electric dipole moment computed from the Stark shifts is 1.472 ± 0.002 D, which compares well with the value 1.475.± 0.006 D reported recently by Fujio Shimita. Convections were applied to K = 3 and K = § lines.

Nine  $0 \rightarrow 1$  rotational transitions of Carbonyl Sulphide, including one Fermi pair and one triplet due to quadrupole interaction of  $^{33}$ S nucleus were observed, accurately measured and assigned. The relative electric dipole moments of OCS in the  $(10^{90})$  and  $(02^{90})$  states and those of  $^{18}$ OCS,  $0^{13}$ CS,  $0^{C3}$ S and  $0^{C3^{4}}$ S in the ground state were computed from the Stark shifts. The relative electric dipole moments for  $0^{13}$ CS and  $0^{C3^{4}}$ S are respectively 1.0057 and 1.0155.

A new technique to distinguish and shift the reflection resonances within the guide from the absorption lines of the gas was developed, and successfully employed.

#### APTER I

### INTRODUCTION

Because of the intensity and richness of its spectrum, amonda has played a major role in the development of microsave spectroscopy. It has provided a large number of easily observable lines on which to try both experimental technique and theory.

The investigation of rotational Raman and IR spectra of amonta has shown that this molecule has pyranidal structure with the shitroger atom at the apex and three hydrogen atoms in a triangle forming the base. The height of the pyranid, the N-H equilibrium distance, and the H-N-H angle are 0.3816 x  $10^{-4}$  cm, 1.0124 x  $10^{-6}$  cm, and 106.67 degrees, respectively. The moments of inertia have very small values  $I^{h}=1^{h}-2.088 \times 10^{-40}$ , ga-cm<sup>2</sup>, and  $I^{C}_{c,p}=4.4141 \times 10^{-40}$  gm-cm<sup>2</sup>. Thus this molecule is an oblate symmetric top belonging to the  $C_{s,p}$ -point Group. Four normal modes of vibrations are associated with this geometrical conformation. Two of them are totally symmetric non-degenerate (As species) yields the other two are doubly degenerate (8 species) vibrations (1). They are illustrated in Fig. 1.1.

The fact that there exist two equilibrium positions of the N-atom on either side of the base, separated by a potential, gives rise to a doubling of each energy level of the whole system of rotational and vibrational states. The transitions from one of the pair of energy levels to the other for all rotational states give rise to what is called the "inversion Spectrum" of ammonta.

Although this inversion spectrum is well studied at frequencies above 12 gHz, and good measurements continue down to 7286 kHz, yet there resain hundreds of lines below the last frequency, and some above it, which have not been observed, most probably because of their low absorptions. This situation becomes apparent on examining Fig. 2.8, which plots the frequencies predicted by an empirical formula first introduced by Costain, and shows the approximate frequencies of a multitude of lines, whose absorptions should decrease as the frequency decreases, or the angular momentum quantum number J increases.

"Atthough there are theories, which will be mentioned in this chapter, concerned with the penetration of the ammonia molecule's contral potential barrier, yet none of them are sufficiently accurate in their predictions to be really useful in microwave spectroscopy, where measurements are readily made to accurates of a few bindrosthe of a Magahertz. Further, since the spectrum is crowded with lines, these theories are unable to indicate the quantum numbers of observed lines by simple comparison of the observed frequencies with their predictions. For example, the frequencies predicted by the theory of Spitho, Stone and Papoussk for the lines with J = 7 differ from the observed frequencies by assumits ranging from 3X to 10X of the observed frequency, while spacing between adjacent lines waries from 3X to 11X of the line frequency.

Formulas of the type introduced by Costnin, fitted to a group of known lines that have been accurately measured give such closer agreement with new observed lines, but it is generally found that the accuracy decreases as the quantum numbers of the line move away from those of the known group. Costnin's original formulation is

not useful at these microwave frequencies below 12.88s, but later modifications of the procedure, such as that by Schnabel et al., are useful for line identification in this range. Rowever, without measurements such as these, there is no critique either of such theories, or of empirical approximations.

One hundred and nineteem fairly strong inversion lines of [70], to lung IV. The absolute intensities of these lines are -10 cm or greater. By maising the temperature of the gas the high rotational levels can be populated, and thus the comparatively weaker lines can also be observed. The object of the present work is to observe, assign and measure some new lines of [70]. These lines are plotted on the graphs of Figs. 2.8 and 2.9. The search for lines was also extended beyond the area marked [New Lines], but it was found impossible to observe more lines with the present apparatus, because in all cases the intensity was below the line of 2 × 10 cm 2.

Although the ground state strongest rotational (0-1) transition line of OCS has been used in Gouble resonance experiments (Mattaglia,
Bozzini and Polacco and others (25)<sup>1</sup>), there is little reference in the
diterature on the weaker components of the 0-1 rotational transitions
arising out of other vibrational states or other inotopic species of
carbonyl sulphide. Also there is no reference to the dipole moments
of different isotopic species of the molecule in different vibrational
states being determined. For this reason, while using the (000) 0-1 OCS
line for calibration purposes, it appeared well to observe some of the
adjuscent lines of carbonyl milphide and to compute the dipole moments
in each case from Stark spectroscopy.

<sup>+</sup> The author apologises that the reference (25) to (30) were introduced at the last moment, and are not in the regular numerical sequence.

### 1.1 Inversion

If the potential energy is plotted as a function of the distance of the N-atom from the N<sub>3</sub>-plane, a curve of the form given is Fig. 1.2 is obtained. There is barrier of height V<sub>1</sub> between the two potential-wells. The nitrogen atom can tunnel through the potential barrier and so, invert the molecular pyramid. The effective magnitude of the potential barrier to finversion depends on the normal mode of vibration excited and the degree of excitation. If this barrier's finite\_(as in NN<sub>3</sub>) each vibrational levie U(v) is epilt into two componert'levil-Q(v+) and U(v-). The splitting of the levels is very much degendent on the barrier height V<sub>1</sub>, becoming zero as the barrier becomes infinite. Because the lowest withrational level is always symmetric, the lower sember of each pair of sub-levels is symmetric and the upper is anti-symmetric to inversion. The transition between the sub-levels of the same vibrational state is called inversion. The inversion-frequency can be further explained by,consideration of the proper potential function.

# 1.2 Some Potential Functions of the Two Fold Inversion Barrier

Various potential functions for the nitrogen atom as it goes through the plane of the hydrogen atoms have been suggested by different authors, with an assumption that the inversion motion is associated with the v<sub>2</sub> beinding mode of amonia and that the inversion problem can be formulated in terms of a single particle, moving under the influence of two fold potential, but restrained to a single co-ordinate.

Numerous theoretical papers dealing with inversion splitting differ in both the form of the potential functions used and approximations made. whi solving the Schrödinger's equation. Thus, Dennison and Uhlenbeck (2) treated the double minimum potential problem through W.K.B. approximations for the ground as well as v2 excited vibrational state. The agreement for the ground state was very good and it was to within 20% for the first excited state.

Manning (3) did a complete analysis for the energy levels of NH3 and ND3 with the potential function

$$V(x) = -C \operatorname{sech}^{2}(\frac{x}{20}) + D \operatorname{sech}^{4}(\frac{x}{20})$$

where C, D, and p are constants. The variable x is the distance of the N-aton from the plane of the N-aton. The energy level differences obtained by him are in good agreement with experimentally observed values for MB3. Approximate barrier heights for MB3 and MD3 obtained thereby were 2072 cm<sup>-1</sup> and 2068 cm<sup>-1</sup> respectively.

Newton and Thomas (4) chose a different potential function

$$V(y) = K(a + by^2)^2 / (1 + y^2)^2$$

where K, a and b are constants, and y is proportional to x. The W.K.f. method was used for the solution of the Schrödinger's equation. This gives results which are comparable in accuracy with those from Manning's potential. But the values calculated for the first excited state are not satisfactory.

Contain and Sutherland (5) have used a potential function which is

more obviously and directly related to the molecular motion in a simple way

$$V = \frac{3}{2} k_r (\Delta r)^2 + \frac{3}{2} k_{\delta} (\Delta \delta)^2$$
,

where Ar and A5 are changes in the bond length and bond angle respectively, and k, are the corresponding force constants. This form of potential gives good values of the potential barrier and the inversion frequencies.

Swalen and Ibers (6) used a potential of the form

$$V(q) = \frac{1}{2} aq^2 + \frac{1}{2} bq^4 + v \exp(-cq^2),$$

where a, b, c and v are the potential constants and q is the normal coordinate of motion. The agreement between the calculated and observed values for the energy levels of Mig and NDg is far better than previously achieved.

. Damburg and Propin (7) used the one-dimensional potential

$$V(x) = K (R^2 - x^2)^2 / 8R^2$$

where 2R is the distance between the minima of the two potential wells.

Davis and Christoffersen (3) obtained the exact solution for a 
one-dimensional time-independent Schrödinger's equation with a symmetric 
double minimum potential constructed from two Yorse potentials:

### .3 Vibration-Inversion Interaction

All the theoretical papers listed above have sized at predicting, the dependence of the inversion splitting on the quantum number no associated with the v<sub>2</sub> bade in which the pyramid height changes most drantically. The relative success of the one-dimensional treatment cones from the fact that the v<sub>2</sub>-normal mode is primarily involved in inversion. But other normal modes of vibration also affect the inversion considerably. This was first realised by Weeks et al. (9). They used potential energy consisting of a double minimum potential amolving the inversion-coordinate, plus the potential of a system of five uncoupled oscillators representing the remaining five vibrational degrees of freedom.

$$V = V_0(x) + \frac{1}{2} \sum_{i=1}^{5} C_i q_i^2$$

The summation is over the remaining five vibrational modes and q<sub>1</sub> is the appropriate vibrational coordinate. The form of the potential used by them is

$$V_{a}(x) = -2F \cdot \cos(\frac{x}{t}) + 2G \cos(\frac{2x}{t})$$

and 
$$V_a(x) = 2 (F + G)$$

F, G and L are positive, and the two minima occur at  $\cos{(\frac{K_0}{L})} = \frac{F_G}{4G}$ . F and G are assumed to be mild functions of the remaining vibrational coordinates, and can be expressed in a Taylor series for small vibrational amplitude.

The current available data on the inversion-splitting in <sup>10</sup>MH<sub>3</sub> (10) are summarised in Table 1.1. An energy level diagram for low lying vibrations is shown in Fig. 1.3.

V. Spirko et al (11) have also developed an effective inversion rotation Hamiltonian to describe the centrifugal distortion and Coriolis interactions in the ground and excited vibration-inversion states of ammonia, but that does not work well in the microwave region.

## 1.4 Effects of Rotation on the Inversion Spectrum of Ammonia

The fact that the molecule is rotating causes the pure inversion y spectrum to be split into a large number of lines, each line corresponding with a given J,K state of a symmetric top molecule. J is the quantum number which represents the total angular momentum of the molecule and the quantum number K represents the component of the total angular momentum along the symmetry axis.

The rotational structure was first resolved by Bleany and
Penrose (12), and theoretically explained by Sheng et al (13). They expressed

In the paper by Weeks et al . was given as r : a misprint.

the observed frequencies in the form

$$v = v_0 + aJ (J+1) + bK^2 + cJ^2 (J+1)^2 + dJ (J+1)K^2 + eK^4 + .$$

This fits the low J and K values better than the high.

Costain (14), applying the exponential dependence of inversion splittings in the Unlembeck-Dennison potential, was able to fit a large number of lines to a six-constant semi-empirical formula of the form

 $v = v_0 \exp \left[ A I \left( J + I \right) + B K^2 + C J^2 \left( J + I \right)^2 + D J \left( J + I \right) K + E K^4 \right]$ This formula always gives v positive contrary to Sheng's formula. This fits all lines in the ground state with  $J \le 16$  to within 1.3 MHz except for the lines with K = 3n, where  $n = 1, 2, 3, \dots$ 

Schnabel et al (15) extended Costain's formula upto higher powers  $viz_{ij}$ ,  $J^{5}$   $(J+1)^{5}$  and  $K^{10}$  and were able to fit 95 lines of  $J^{5}$ NN13 and 46 lines of  $J^{5}$ NN13 with an accuracy within 0.48 NN2 and 0.39 NNz respectively.

The anomalous deviations of K = 3 lines from the above formulae have been explained by Mislaen and Dennison (16) on the basis of splitting of |K| = 3 levels by a vibration-rotation interaction. They derived a formula for the doublet splitting of |K| = 3 levels.

$$\Delta v = (-1)^{J} \alpha J(J+1) [J(J+1) - 2] [J(J+1) - 6]$$

where  $\alpha$  was called a rotation-vibration constant, but it is really a function of J(J+1).

## 1.5 Selection Rules

The selection rules for pure inversion transitions in a symmetric top molecule are

### 1.6 Stark Effect

When an electric field is applied to a polar gas, it interacts with the electric dipole, causing a splitting of the rotational energy levels,

which results in the appearance of fine structure of the rotational level spectrum. This is known as Stark effect.

The electric dipole moment can be represented by a vector whose magnitude is measured by the distribution of charge in the molecule and the distance between the centres of the charges, i.e.

where  $e_i$  is the charge on the i<sup>th</sup> particle and  $\tilde{t}_i$  is the vector distance of the i<sup>th</sup> particle from the origin of a coordinate system fixed in the molecule. The summation is over all the nuclei and the electrons in the molecule.

If the stark effect perturbation is considerably smaller than the rotational energy level spacing, perturbation theory, can be used to calculate the Stark eplittings. The perturbation term H<sup>(1)</sup>s the interaction energy between the electric field E and the molecular dipole moment F. The interaction-energy is expressed as

$$H^{(1)} = -\overset{\rightarrow}{\mu} \cdot \overset{\rightarrow}{E}$$

The first order perturbation energies are obtained from an average of the perturbation term  $\mathbb{H}^{(1)}$  in the Hamiltonian

over the unperturbed state, i.e.,

$$E_{J}^{(1)} = \int \Psi_{J}^{(0)} H^{(1)} \Psi_{J}^{(0)*} d\tau,$$

where the  $V_J^{(0)}$  is the wave function for the unperturbed rotor, and  $H^{(0)}$  is the Hamiltonian for the field-free rotor.

The second-order energies are

$$E_{J}^{(0)} = E_{J}^{(0)} - E_{J}^{(0)} = \frac{E_{J}^{(0)} - E_{J}^{(0)}}{[N A^{2}, (0) H(1) A^{2}, (0) + GL]}$$

The transitions involving inversion obey the selection rule

$$\Delta J = 0$$
,  $\Delta K = 0$ ,  $\Delta M = 0$ ,  $K \neq 0$ 

where M is the quantum number pertaining to the projection of 3 in the E-direction. The Stark effect of the inversion doubling of aumonia represents a special case in the sense that the dipole-moment of amnonia is only "semi-permanent" because of the inversion splitting. Hence it does not show the first order Stark effect. The second order Stark shift of ammonia is given by (17)

$$\Delta v = \frac{0.5065 \ \mu^2 \ E^2}{v_0} \left[ \frac{\bar{KM}}{J(J+1)} \right]^2$$

where v is in MHz,  $\mu$  in Debye units, and E in volts per cm. Because the E<sup>2</sup> contributions to energy are degenerate in  $\pm E$ , only J+1 resolvable Stark lines -result. All levels for N  $\neq$  0 are doubly degenerate in  $\pm M$ . The maximum aplitting occurs for M = J.

The expression for the Stark shift for 0+1 rotational transitions of OCS is given by (27)

$$\Delta v = \frac{0.1351 \, \mu^2 E^2}{v_0}$$

For this transition there is only one Stark component, whose integrated intensity equals that of the normal line. This is an advantage in the measurements of the dipole and quadrupole moments of the carbonyl sulphide molecule.

# 7 Rotational Spectra of Linear Polyatomic Molecules

Molecules with permanent electric dipole moments give rotational spectra, and for these the selection rule is  $\Delta J = \pm 1$ . This gives for the change J + J + 1

$$v = 2 B_V(J+1) - 4 D_V(J+1)^3$$

 $B_{\chi V}$  the effective rotational parameter for the vibrational state v, is given by

$$B_{v} = B_{e} - \frac{\Sigma}{i} \alpha_{i} (v_{i} + \frac{d_{i}}{2})$$

where B is the rotational constant for equilibrium configuration. The summation extends over all vibrations with the degenerate ones included only once. v<sub>4</sub> is the vibrational quantum number and d<sub>4</sub> is the degree of degeneracy for the i<sup>th</sup> mode of vibration. For a non-degenerate node d<sub>4</sub> = 1, for a doubly degenerate mode d<sub>4</sub> = 2, etc. D<sub>5</sub> is the centrifugal distortion constant for the vibrational state.v. a<sub>4</sub> is a small constant which measures the correction in 8 for that mode.

## .8 Fermi Resonance

In a polyatomic molecule it may happen that two vibrational levels belonging to different vibrations (or combinations of vibrations) may have nearly the same energy, that is, may be accidently degenerate. As was first recognized by Fermi in the case of OO<sub>2</sub>, such "resonance" leads to a perturbation of the energy levels. The calculation of these perturbations is a standard method of quantum mechanics provided that the perturbation function is known.

The perturbation depends on the value of the matrix element  $\mathbf{W}_{\text{nd}}$  of the perturbation function  $\mathbf{W}_{\text{n}}$ 

$$W_{ni} = \int \psi_n^{\delta} W \psi_i^{(o)} d\tau \qquad (1)$$

The perturbation function W is here essentially given by the anharmonic terms in the potential energy, while  $\psi_0^0$  and  $\psi_1^{10}$  are the zero approximation eigen functions of the two vibrational levels that perturb each

other. Since W is totally symmetric, W  $_{ni}$  will be zero unless  $\phi_n^o$  and  $\phi_n^o$  are of the same species (i.e., of the same symmetry b type).

If the resonance is fairly close, the magnitude of the shift can be obtained according to the first-order perturbation theory from the secular determinant

$$\begin{bmatrix} E_n^0 - E & u_{in} \\ w_{ni} & E_1^0 - E \end{bmatrix} = 0$$
 (2)

where E and E are the unperturbed energies.

The separation of the perturbed levels is given by

$$\Delta W = (4|W_{n1}|^2 + \delta^2)^{\frac{1}{2}} \tag{3}$$

where  $\delta = E_n^0 - E_1^0$  is the separation between the unperturbed levels.

Most of the pairs of OCS levels which pertrub each other are those with quantum numbers  $(v_1,v_2)^{k,l}$ ,  $v_3$ ) and  $(v_1-1,v_2+2^{k,l},v_3)$ .

Such a pair of levels will be designated by subscript 1 and 2, respectively. The first pair of perturbing levels in OCS are (1,0°,0) and (0,2°,0). It can be shown that

$$W_{12} = k \left\{ v_1 \left[ \left( v_2 + 2 \right)^2 - k^2 \right] \right\}^2$$
 (4)

where W<sub>12</sub> is the interaction energy and k is a constant for a given molecule. The perturbed wave functions are a mixture of the unpersturbed wave functions and are given by

$$\psi_1 = a \ \psi_1^0 - b \psi_2^0, \ \psi_2 = b \psi_1^0 + a \psi_2^0,$$
 (5)

where 
$$a = \frac{\left[\left[\delta^2 + 4\right] \left|\left|\left|\left|\left|\right|\right|^2\right|^{\frac{1}{2}} + \delta\right]}{2\left[\delta^2 + 4\right] \left|\left|\left|\left|\left|\left|\right|\right|\right|^2\right|^{\frac{1}{2}}}$$

$$\dot{\mathbf{b}} = \frac{\left[ [6^2 + 4 [\mathbf{W}_{12}]^2]^{\frac{1}{2}} - 6 \right]^{-\frac{1}{2}}}{2[6^2 + 4 [\mathbf{W}_{12}]^2]^{\frac{1}{2}}}$$
(6)

The actual B values of the interacting levels are given by

$$B_1 = a^2 B_1^0 + b^2 B_2^0, B_2 = b^2 B_1^0 + a^2 B_2^0$$
 (7)

since  $a^2 + b^2 = 1$ 

$$B_1 + B_2 = B_1^0 + B_2^0$$
 (8)

The unperturbed value of  $a_2$  is found from the separation between the rotational levels of states (000) and (01°0). The frequency shift of the  $(02^0)$  level due to Fermi resonance may be obtained from the known value of  $a_2$ . The unperturbed value of  $a_1$  may be determined since the frequency change of the (100) state must be equal and opposite to that of  $(02^00)$ . Then from equation (7)  $a^2$  and  $b^2$  can be calculated and  $W_{12}$  obtained using equation (6).

# 1.9 Quadrupole Interaction by a Single Coupling Nucleus

If a system coptains a quadrupole mucleus, the interaction of the quadrupole with the external electrons couples together the nuclear spin I and the rotational angular momentum I to form a resultant F, where the quantum number F takes one of the values

$$F = J + I$$
,  $J + I - I$ , . .  $[J - I]$ .

From quantum mechanical considerations the first-order quadrupole coupling energies for a single coupling nucleus in a linear molecule are shown to be

$$\mathbf{F}_{\mathbf{q}} = - \text{(eqQ) Y (J, I, F)}$$

where (eqQ) is referred to as the quadrupole coupling constant, and

and Y(J, I, F) as the Casimer function.

$$Y(J, I, F) = \frac{3/4}{2(2J-1)} \frac{C(C+1) - I(I+1) * J(J+1)}{(ZJ+3) I(2I-1)}$$

....

The selection rules for hyperfine transitions in rotational absorption spectra are

$$\Delta J = +1$$
,  $\Delta F = 0$ ,  $\pm 1$ ,  $\Delta I = 0$ .

The rotational frequencies perturbed by quadrupole coupling are given by

where v is the unperturbed rotational frequency, and F' corresponds to the lower state relative to the rotational level without hyperfine structure.

### CHAPTER II

#### EXPERIMENTAL APPARATUS AND TECHNIQUE

## 2.1 Description and Discussion of Components

A microwave spectrometer essentially consists of (1) a source of monochromatic radiation with proper frequency-range, (2) a frequency-monitor, (3) an absorption cell containing the gas under investigation, (4) a detector, and (5) a device for spectral presentation. In this section a brief description of these components will be given.

### 2.1a Sources

The microwave radiation sources employed here were two Watkins—
Johnson Backward Wave Oscillators, model WJ 2020-2 and WJ 2019-1, using the X
and J bands respectively. The J band has frequency range from 4.0 to 8.0 GHz am
the X band, from 8.0 to 12.4 GHz. The power output from these oscillators
is 50 to 100mW.These B.W. Oscillators were mounted in the Hewlett-Packard
Sweep Oscillator, Nodel 8690 A. The frequency-sweep was controlled by
varying the electrode voltage of the B.W.O. tube by means of a 50 K chm
ten-turn potentiometer, connected to the shaft of a 4 to 24 volts D.C. motor.
It was possible to obtain a wide variety of slow sweep rates by warying the
driving voltage of the motor or by adjusting Af of the sweep oscillator.

#### 2.1b Frequency Measurement

A portion of the microwave power output from the B.W. Oscillator is coupled out to the frequency measuring device by means of a 10 db-directional coupler. The frequency is measured on a Newlett-Packard Electronic Counter, Model 5245 i.,

equipped with the Hewlett-Packard frequency converter (3 to 12.4 GHz),

The major portion of the microwave power goes to the absorption cell via variable attenuator and a series of waveguide sections.

## 2.1c The Absorption Cells

The absorption cells were made of ten-foot pieces of 8-band . . waveguide of interior dimensions 2.840" x 1.340", with a central flat plate (called the Stark electrode) parallel to the broad faces of the guide and so perpendicular to the microwave electric field. In one of the cells the plate is supported by strips of teflon in which guiding grooves are milled (Fig. 2.1). In the other absorption cell the plate is supported on six equidistant pillars of insulating material. Connection to the Stark electrode is made by a brass rod through a hermetic seal in the side-wall of the coll, which terminates in a screw threaded into the plate. By mounting the Stark electrode parallel to the broad faces of the guide, interference with the propagating radiation is reduced to the minimum, as the microwave electric field in the dominant TE10 mode is always perpendicular to the electrode. Nevertheless, the presence of the electrode results in appreciable attenuation and also tends to produce reflections. The latter are reduced somewhat by tapering the ends of the electrode, as shown in Fig. 2.1a. The absorption cells are sealed at the ends with Mylar windows, supported on rubber 'O' rings. The cells are constructed of oversized waveguide so as to virtually eliminate saturation broadening. Tapered transition sections of waveguides are attached to the ends to facilitate further attachment of the appropriate X and J band equipment. The interior dimensions of the X and J band waveguides are 0.900" x 0.400" and 1.372" x 0.622", respectively. The

cut-off frequencies for the dominant TE<sub>10</sub> mode for the S, J, and X band waveguides are 2.078 GHz, 4.301 GHz and 6.557 GHz respectively.

It is common practice to use overafized guide, such as 5 band guide, for the main absorption cell to avoid saturating the molecules with excessive radiation, (also to avoid excessive guide losses in the case where the frequencies exceed 20 girs). Quoting from Walter Gordy, "Since there are no couplers, T-sections, alots, etc. in the absorption cell, it is possible to use oversized guide without exciting unwanted modes. ...... Here at Duke we have used 5-band guide (3" x 1½") very effectively for absorption cells in the region from 3 to 5 mm wave-leagth.

...... In other regions oversized cells are desirable to avoid saturating the solecules with radiation."(29)

It is, of Acourse necessary to connect the different sized guides with horns, or tapered sections of guide, and this has been the practice in microwave spectroscopy for many years. In the case mentioned by Walter Gordy the ratio of the 8-band width to that of the 3 to 5 mm band guide would have been 2.84"/0.11" = 25.8, while in this laboratory the ratio is only 2.84"/0.90" = 3.16, yet Cordy stated that they had "no more than the usual trouble with reflections".

The microwave power passes, as shown in Fig. 2.5 through a

directional coupler, a variable attenuator, a series of tapered matching vavequide sections, and then into the absorption cell, which holds a small sample of the gas. The attenuators control the amount of micorwave power allowed to pass through the absorption cell, and also attenuate the unwanted reflected waves generated chiefly at the ends of the Stark electrode and at the windows. The directional coupler placed directly after the source does not provide any appreciable attenuation between source and detector, but provides IX of the microwave power to the frequency meter for frequency measurement.

### 2.1d Vacuum System

The cells were directly connected to a vacuum system by an outlet through their broad sides about one third along their length. The vacuum system (Fig. 2.2) consisted of a number of stop-cocks and cold traps of glass. The vacuum system and the absorption cells were evacuated by a garder of glass. The vacuum pump, Nodok 1802). A liquid nitrogen trap was used to condense most of the gas in the cold trap before it reached the pump. The trapped gas was transferred to a glass bulb fitted with stop-cock and stored therin for future use. Fresnure was measured with a Hastings Vacuum Gauge, Model SV-1, which was calibrated with a Nolcod Cauge. The calibration curve interproduced in Fig. 2.6.

## 2.1e Signal Modulation

If an electric field is applied to a polar molecule its absorption frequencies are shifted because of the Stark effect. If at some instant the B.W. Oscillator frequency coincides with that of an absorption line, and a periodic electric field is applied, then there will be a corresponding time variation in the power detected by the crystal, since the Stark components of the line are shifted relative to the source frequency. The switching can be done electronically at radio frequency, and the resulting modulation of the microwave power absorbed by the gas can then be detected by a radio receiver tuned to the modulating frequency. This is the principle of the Stark modulation spectrometer introduced by Humbes and Williams (18).

In addition to increasing sensitivity by avoiding low frequency noise, this method allows the detection of the absorption line, eliminating to a-great extent the detection of the spurious signals arising out of mismatch in the microvave line.

In the present experimental set up, the signal was amplitude modulated by a zero-based 100 K Hz square wave generator, manufactured by Industrial Components Incorporated. The voltage was continuously variable up to 2000 volts. The source oscillator was electrically swept over the absorption line at a rate which was alow compared to the modulation frequency, so that the absorption line was detected and displayed in the usual manner. In course of the sweep, when the oscillator frequency coincided with the frequency of some Stark line, the latter was detected and displayed inverted relative to the zero-field line. This was made possible by the use of a phase-sensitive detector. The Stark pattern was then used to identify the transition and evaluate the dipole moment.

\*The amplifier is tuned to 100  $^{\rm KHz}$  and the phase-sensitive detector used with a band width of either 1.0 or 0.1 Hz.

# 2.1f Detection

The output from the absorption cell was detected by Hewlett-Packard Crystal Detector, Model X424 or J424A (negative biased). The output of the crystal detector was fed into a preamplifier, and then to a receiver tuned to 100 KHz (both manufactured by Industrial Components Incorporated).

The crystal itself consists of a small piece of a semiconductor

material, in contact with a fine tungston whisker.

Such a system behaves as a rectifier for current at microwave frequencies. The crystal is sounted on a holder whose outer caping is in contact with the waveguide walls. The inner confluctor, to which the tungston whisker is connected, leads across the waveguide, and so acts as the antenna for collecting microwave radiation, and the rectified output signal passes to the coastal b.N.C. connector. The assemply of the X424A crystal detector is shown in Fig. 2.3.

#### 2.1 g. Display

For the display of the output signal from the 100 Mis receiver either a Hewlett-Packard 7035A X-Y recorder or a 71008 strip chart recorder was used. To the preliminary search of the absorption lines the X-Y recorder, and for the final analysis of the lines the atrip-chart recorder was used. The complete block disgram of the picrowave spectrograph is shown in Fig. 1.5.

## 2.2 Experimental Technique

## 2.2a Search of Lines

The absorption cell and the glassware were normally evacuated to a pressure of 0.002 torr. In fact, the pumping out operation was continued for

several days by intermittent heating of the guide to ensure that the absorption cell and the rest of the vacuus system were completely free from any trace of absorbed games. Further, the absorption cell was flushed several times with 99.99% <sup>18</sup>833 gas supplied by Matheson of Canada Ltd. by letting in the gas through the inlet. Each flush was followed by evacuation of the vacuum system. This process was repeated assweral times to ensure that very little of any foreign gas remained in the absorption cell and the glass wares.

Finally, a fresh sample of ammonia gas from the bottle was introduced into the absorption cell until the pressure rose up to 1 torr. Then the excess of the gas was removed from the cell by pumping it out and cooling in the trep until the pressure went down to the optimum level, i.e., to 0.01 torr.

Using the formula given by Schmabel et al. (15), a an empirical spectrum was generated. The intensities of these lines at 100°C were also calculated. After raising the temperature of the guide to about 90°C, search for those lines whose theoretical intensities were of the order of 2 x 10°° cm<sup>-1</sup>, was made on a slow-sweep chart recorder. The temperature could not be raised further, as the seals in the absorption cell started leaking at higher temperatures.

### 2.2b Identification of Reflection Resonance-Lines

To identify the resonance-lines within the guide, the absorp tion cell was highly evacuated with intermittent heating so as to leave little trace of 14 NH; gas in the vacuum system. The output voltage of the crystal was directly fed to the X-Y recorder, and again a sweep was taken at the steps of 100 MHz for the frequency range 4.0 to 12.4 GHz as done previously with the gas in the cells. Many/lines reappeared with diminished intensity. These were, possibly, the resonance lines within the guide. As a further check on the nature of the origin of these lines, the experiment was repeated after raising the temperature of the guide by 50° to 60°C. These lines appeared again, but were displaced to the lower frequency side by an amount, which depended on the thermal expansion of the guide. As explained below, this frequencyshift due to temperature-variation is the characteristic associated with the resonance lines only. In this manner, the resonance lines within the guide were unambiguously identified and eliminated from the list for further investigation.

# 2.2c Shifting the Resonance Lines by Heating the Guide

of distinguishing absorption due to the material under study from the unwanted resonances set up within the waveguide system itself. Such standing waves arise from reflections between slight discontinuition in the waveguide

One of the most serious problems in microwave spectroscopy is that

particularly at the coupling joints, windows, etc. These resonances overlap and obscure the Stark lines as well.

Working on the idea/seggested by Dr. R. Tipping a method of moving the resonance lines to lower frequency was devised. The remeant frequency is given by

where v = velocity of the microwaves in the guide,

L = length of the absorption cell.

When the absorption cell is heated, its length increases to

$$L' = L(1 + \alpha \Delta T),$$

where  $\alpha$  = the temperature-coefficient of the material of the guide

Therefore, the frequency of the resonance line changes to

$$f' = \frac{nv}{2L}, = \frac{nv}{2L(1 + \alpha \Delta T)}$$

Thus, the frequency-shift  $\Delta f = f' - f$ .

$$= -\frac{nV}{2I} \cdot (1 - \frac{1}{1 + \alpha \Delta T})$$

$$= -\frac{f \cdot \alpha \Delta T}{1 + \alpha \Delta T}$$

$$= -1 \cdot \alpha \Delta T$$

As a typical example, let f = 8000 MHz, a (brass) = 19 x 10<sup>-6</sup>, AT = 50<sup>o</sup>C, then Af = -7.6 MHz. Thus, by raising the temperature of the guide, the resonance lines could be newed to a considerable amount to lower frequency side, whereas the absorption lines due to games showed no such shift. This method was used not only to distinguish resonances from the absorption lines.

but also to forestall the obscuring of the Stark lines caused by these unwanted tignals overlapping the wanted lines.

### 2.2d Voltage Calibration of Stark Cell

In spice of the utwost care in the design of the Stark modulation cell, the distance between the septem and the walls of the guide may not remain enchanged throughout its length, causing a watistion in the electric field and the consequent uncertainty in the precision in the knowledge of the field strength. The average value of the field may be obtained by calibration with a substance whose dipole moment is known accurately. For waterage calibration of the guide fiers, carbon oxysulphide ( $^{16}\mathrm{C}$ )  $^{12}\mathrm{C}$ ) was used as calibrant ( $^{16}\mathrm{C}$ ) in the ground state = .7149D). The second order Stark shift of the ground state 0  $\rightarrow$  1 transition ( $^{1}\mathrm{C}$ ) = 12162.97, Min) was measured for different voltages and the electric field-strength (volta/cm) was calculated from the formula

$$E = \frac{1}{\mu} \sqrt{\frac{v_0 \, \Delta v}{0.1351}}$$

where Av - Stark shift in MHz and V-0.7149D. A graph was plotted between the voltmeter reading V and the electric field graength E. This was done for both the guides. The calibration-curves are reproduced in Fig. 2.7.

# 2.2e Analysis of the Lines

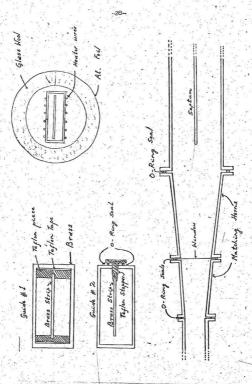

For accurate measurement of frequencies of the absorption lines and the resolution of Stark lines, the output frequency-variation was controlled by a 50 K chm ten-turn potenticester, slowly driven by a 4 to 24 volts D.C. motor via a worm gear. By keeping the driving voltage at 20 volts and maintaining Af a 200 MHs, a sweep rate of 0.1 to 0.2 MHs per minute was obtained. The crystal current, which is also a measure of the signal strength, was kept at 120 Ms. The bandwidth of the 100 KHz receiver was selected to be 0.1 Hz . The display of the output signal from the 100 KHz receiver was made on the strip chart recorder, the paper speed being maintained at 0.2 inch per sinute. The voltage scale usually chosen was 250 mV full scale deflection.

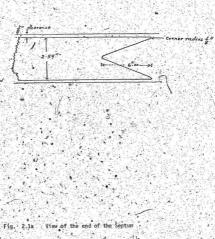

## 2.2f Calibration of the Frequency-Meter

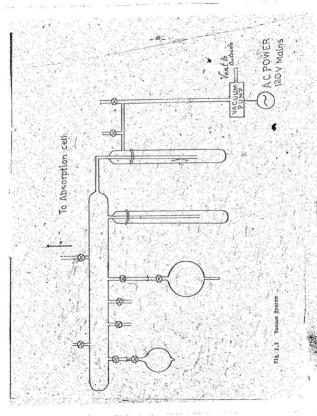

Using the ground state 0-1 rotational transitional frequency of OCS as the frequency standard, the HP frequency-seter was calibrated. The everage result of the 96 samples was 12162.970 MHz. The theoretical value is 12162.984 MHz for the J = 2-3 lines of OCS and the Landholt-Bornstein value for D of 1.31 x 10<sup>-5</sup> MHz. The weighted average for the ratio of the theoretical frequency and the observed frequency is 1.0000011. The correction to the observed frequencies is 40.014 MHz, which is less than the r.m.s. error of 40.0225 MHz. Hence in the present work no corrections were applied to the frequency-in needed, because this is sufficient to calibrate the crystal in the frequency-meter.

The frequency of a rotational line is given by the formula,  $v = 2 \text{ B } (3+1) - 4 \text{ D } (3+1)^3$ ,

where J is the rotational quantum number of the lower state. Obviously, for the  $0 \rightarrow 1$  transition , J=0.

### CHAPTER III

#### RESULTS AND DISCUSSION

# 3.1 Ground State Inversion Lines of 14NH3

As a result of careful investigations 15 new ground state inversion lines of \$^{1}MH\_{3}\$, including one K \* 3 and one K  $\geq$  6 lines, were observed. The frequencies of the newly observed lines were accuractly measured by taking the average of a number of observations at the peak of the absorption lines in the up and down slow sweeps. The results are given in the Table 3.1 and the Figures 2.8 and 2.9.

Corrections were applied for K = 3 and K = 6 lines, using the values of the rotation-vibration function, determined in this laboratory (26) as well as that given by Schnabel et al. (15) in the Nielsh and Dennison's formula (16).

The corrections for K = 3 are expressed as

$$\delta v' = (-1)^J \alpha_s J(J+1) (J(J+1)-2)(J(J+1)-6)$$

with  $\alpha_{\rm T} = 3.74044 \times 10^{-4} - 6.097 \times 10^{-6}$  (J-3) MHz (Schnabel)

or, 
$$\alpha_J = 3.57582 \times 10^{-4} \left[1 - \frac{J(J+1)}{1675.63}\right]$$
 MHz (Arthur G. Earle.)

The corrections for K = 6 are expressed as

where  $\phi(J) = J(J+1)(J(J+1)-2)(J(J+1)-6)(J(J+1)-12)(J(J+1)-20)(J(J+1)-30)$ 

The assignments of the newly observed lines were made on the basis of the emptrical formula developed by Constan (14) and later by Schmable at al. (15). Further, the Stark shifts of the lines 6438.64 MHz and 7969.32 MHz are consistent with the theoretical values, which confirms the correctness of the assignments.

Because the J-values ranged from 13 to 19 in these lines, it was difficult to resolve the separate Stark components in their Stark patterns. However, as can be seen Figures 3.12 and 3.14, the position of the outer component, with My = J, can be estimated within 10.15 Mis, defining the outer limit of the Stark lines at the Stark voltage used. The square of the dipole moment can then be found by using-the formula for the Stark shift of Ammonda-saven in section 1.6, with N = J.

The outer limits of the Stark lines of 6438.64 MHz and 7969.32

MHz at different voltages were observed and the dipole moment was calculated from each observation. The average value of the dipole moment is 1.472 ± 0.002 D which is in good agreement with the value 1.475 ± 0.0000 D obtained by Fujio Shinkau (19) by Stark spectroscopy using CO<sub>2</sub> and N<sub>2</sub>O lasers. The Yesults of the Stark analysis of these lines are given in Tables 3.2 and 3.3. The frequencies of the outer limits of the Stark lines were plotted against the Stark voltages. All the points lie on straight lines. The graphs are shown in Figures 3.1 and 3.3. Due to high values of J and low intensities of these lines the individual Stark lines could not be resolved. As a check that these lines were due to the gas "NH3 slow sweeps were taken after pumping out the gas for one hour maintaining the other conditions as before. The intensities of the lines reduced to approximately 1/10 of the original ones.

## 3.2 J = 0+1 Rotational Transitions of Carbonyl Sulphide

Mine lines of Carbonyl-Suphide were-observed, accurately measured and assigned. The assignments of the "ubrational quantum numbers and isotopic constituents were made on the basis of the previous works reported in NBS monograph 70, Volume IV, for J = 1+2, 2+3 and 3+4 transitions and also on the basis of the values of the constants given in the book by Landolt-Bornstein (20).

The triplet structure due to the quadrupole moment of <sup>318</sup> nucleus in the 0°1 trensition was completely resolved. Using the value of the quadrupole coupling commant (eq0) = -29.07-80% obtained by Rabback et al. (21) and the centre of gravity v<sub>0</sub> = 12009.793 Min the calculated line positions agree with those observed within the experimental error of 0.02 Min.

From Stark analysis, the value of dipole moment of carbonyl sulphide for different inotopic forms and different vibrational states was obtained. The results of the Stark analysis are given in tables 3.5 and 3.13. The graphs of the Stark shifts vs. Stark voltages are shown in the figures 3.5 and 3.11.

The lower frequency scales in the Fig. 3.12 through 3.26 correspond to the sweeps taken after the 1 NH 3 gas was pumped out for about one hour.

## 3.3 Summary of Results

Pifteen new ground state inversion lines of <sup>16</sup> NH<sub>3</sub> were observed, accurately measured and assigned. The results of the Stark analysis of two of these lines confirmed the assignments, which are mainly based on the extrapolation of the empirical formula of Schnabel of al. and the computations by C. Pederson and Faul Gillard of MNN. The dipole moment computed from the Stark shifts of these two lines is 1.472 ± 0.002 D, which is an good agreement with the value of 1.475 ± 0.066 D reported by Fujio Shimizu (19) recently. The r.m.s. deviation of the predicted frequencies from the observed frequencies is 10.64 MNz with Schnabel's formula and ±0.36 MNz with MNN computations. The agreement between the theoretical frequencies from the seaf-compifical formulae of Schnabel et al. for K = 3 and K = 6 lines and the observed frequencies is good in view of the large shift for J = 13

Nine 0-1 rotational transitions of carbonyl sulphide very observed, accurately measured and assigned. Two of these were identified as Fermi pair and three of the constituted a triplet due to the quadrupole action of the 31s nucleus. The r.m.s. deviation between the calculated and observed frequencies, is 10.014 MHz, which is less than the experimental error of 10.023 MHz. From the Stark analysis the relative dipole moments of (100) and (02°0) vibrational states of OCS and (000) viates of 100S, 013CS, 003S and 003Ms were determined. The results are given in Table 3.14. The following points are to be noted.

The dipole moment of OCS is less in the vibrational states
than in the ground state. It is 0.825% less in (100) state

and 2.224% in the (02°0) state. The value of the disole moment is the (01°0) state is reported to be 1.53% less than that in the ground state by Reinarts at al. (24).

The variation of the disole moment with isotopic quobstitution is also appreciable. The substitution of 180, 190 and 195 in 005 increases the disole moment by 1.83%, 0.294%, and 1.413%, respectively. However, there is at large decrease of 12.44% in the value of the disole moment by isotopic substitution of <sup>33</sup>S, which has the quadrupole conntant of 2.90 of NHz.

A variation of dipole moment with vibrational state is intuitively reasonable, since the molecular structure and the charge distribution differ from those in the ground state. The dipole moment variation can be treated approximately by considering the change of the effective bond length with vibrational quantum number. The change in the dipole moment depends not only on the bending or change in the relative directions of 0-C and C-S bonds, but also on the electronic wave functions involved in each bond due to vibration. Since each isotopic species has slightly different vibrational energy the variation of dipole moment with isotopic substitution is also reasonable.
